

# Bayesian Learning lab2-revised

Joris van Doorn // Weng Hang Wong

5/18/2020

## 1. Linear and polynomial regression

The dataset *TempLinkoping.txt* contains daily average temperatures (in Celcius degrees) at Malmslätt, Linköping over the course of the year 2018. The response variable is *temp* and the covariate is

$$time = \frac{\text{the number of days since beginning of year}}{365}$$

The task is to perform a Bayesian analysis of a quadratic regression

$$temp = \beta_0 + \beta_1 * time + \beta_2 * time^2 + \epsilon, \epsilon \sim^{iid} N(0, \sigma^2)$$

a.

Determining the prior distribution of the model parameters. Use the conjugate prior for the linear regression model. Your task is to set the prior hyperparameters  $\mu_0, \Omega_0, \nu_0$  and  $\sigma_0^2$  to sensible values. Start with  $\mu_0 = (-10, 100, -100)^T, \Omega_0 = 0.01 \cdot I_3, \nu_0 = 4$  and  $\sigma_0^2$ . Check if this prior agrees with your prior opinions by simulating draws from the joint prior of all parameters and for every draw compute the regression curve. This gives a collection of regression curves, one for each draw from the prior. Do the collection of curves look reasonable? If not, change the prior hyperparameters until the collection of prior regression curves agrees with your prior beliefs about the regression curve.

**Predicted Temperature with given hyperparameters**

**Predicted Temperature with given hyperparameters**

**Predicted Temperature with changed hyperparameters**

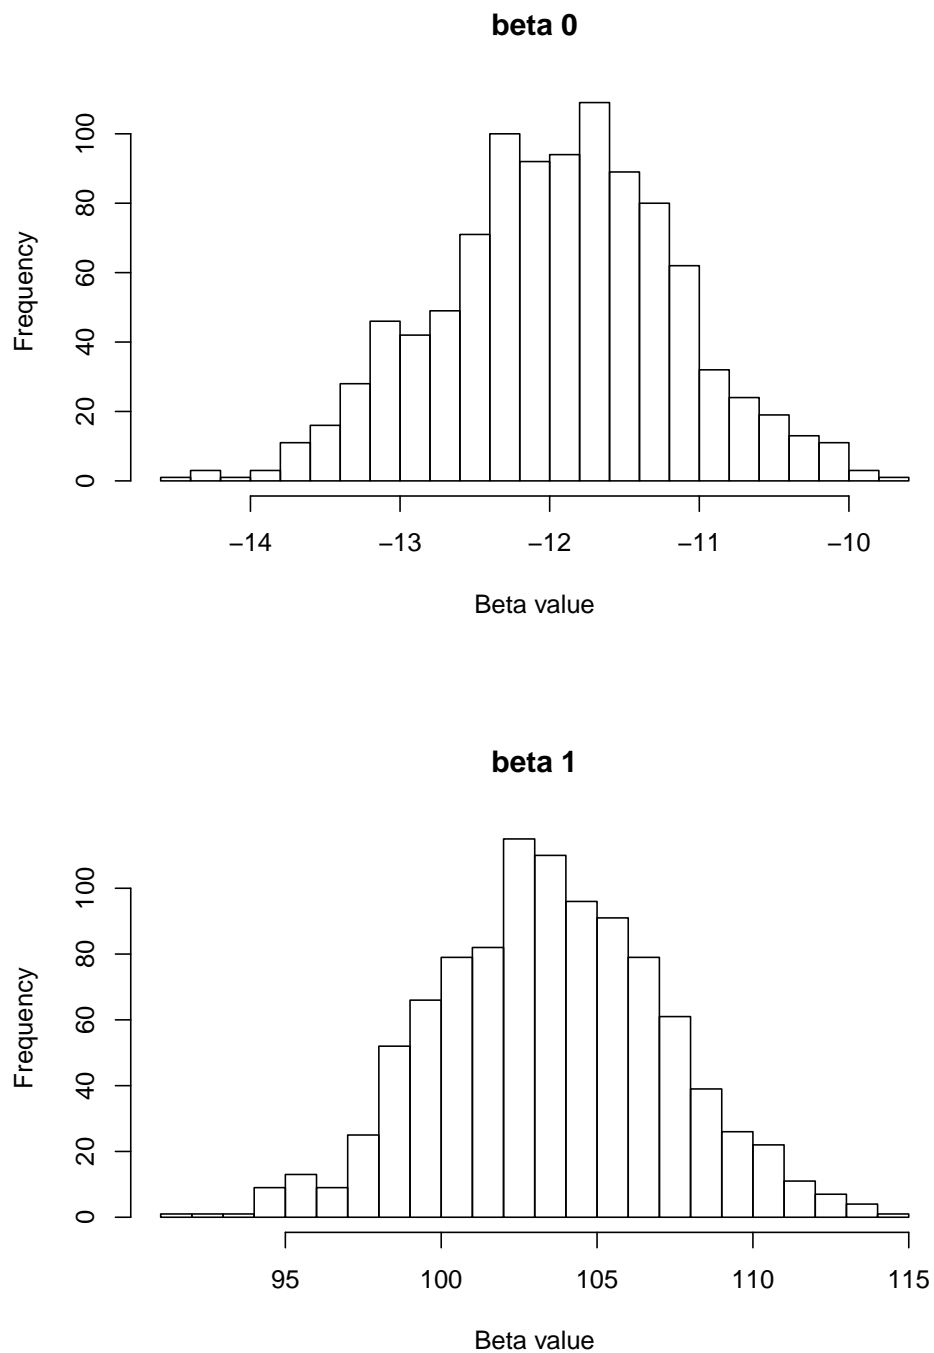

b.

Write a program that simulates from the joint posterior distribution of  $\beta_0, \beta_1, \beta_2$ , and  $\sigma^2$ . Plot the marginal posteriors for each parameter as a histogram. Also produce another figure with a scatter plot of the temperature data and overlay a curve for the posterior median of the regression function  $f(\text{time}) = \beta_0 + \beta_1 \cdot \text{time} + \beta_2 \cdot \text{time}^2$ , computed for every value of time. Also overlay curves for the lower 2.5% and upper 97.5% posterior credible interval for  $f(\text{time})$ . That is, compute the 95% equal tail posterior probability intervals for every value of

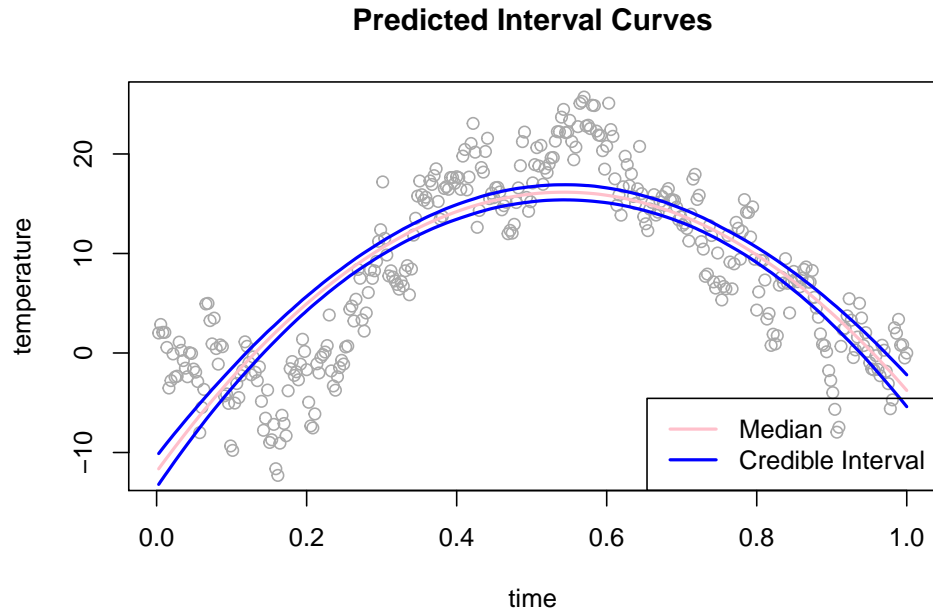

time and then connect the lower and upper limits of the interval by curves. Does the interval bands contain most of the data points? Should they?

From the graph below, the parameters are simulated from the joint posterior distribution. The marginal posteriors for each parameter  $\beta_0, \beta_1, \beta_2$ , and  $\sigma^2$  are shown below.

Here is a scatter plot of the temperature data with the median and credible interval curves. However, most of the data points are not contained in the 95% posterior credible interval, they should not contained most of the data points, since it didn't include the  $\varepsilon$  in the regression function and the uncentainty parameter here has particular probability.

**c.**

*It is of interest to locate the time with the highest expected temperature (that is, the time where  $f(\text{time})$  is maximal). Let's call this value  $\tilde{x}$ . Use the simulations in b) to simulate from the posterior distribution of  $\tilde{x}$*

The first derivative of  $f(\text{time})$  will be maximal when it equal to zero.

$$y = \beta_0 + \beta_1 \cdot x + \beta_2 \cdot x^2$$

$$0 = \beta_1 + 2\beta_2 x$$

$$\tilde{x} = \frac{-\beta_1}{2\beta_2}$$

**##** The expected highest expected temperature is 0.5430181

d.

Say now that you want to estimate a polynomial model of order 7, but you suspect that higher order terms may not be needed, and you worry about overfitting. Suggest a suitable prior that mitigates this potential problem. You do not need to compute the posterior, just write down your prior. [Hint: the task is to specify  $\mu_0$  and  $\Omega_0$  in a smart way.]

To prevent overfitting we suggest adding a regularization term. The proposed prior would like as follows:

$$\beta_i | \sigma^2 \sim^{iid} N(0, \frac{\sigma^2}{\lambda})$$

where  $\lambda$  will be the smoothness/shrinkage/regularization term.  $\Omega_0$  and  $\lambda$  are relate as  $\Omega_0 = \lambda I$ . A change in  $\lambda$  does not directly affect  $\mu_0$ . However, it does influence  $\mu_n$  through  $\Omega_0$ . The larger  $\lambda$  is, the more shrinkage.

## 2. Posterior approximation for cassification with logistic regression

The dataset *WomenWork.dat* contains  $n = 200$  observations (i.e. women) on the following nine variables:

a.

Consider the logistic regression

$$Pr(y = 1|x) = \frac{e^{x^T \beta}}{1 + e^{x^T \beta}}$$

where  $y$  is the binary variable with  $y = 1$  if the woman works and  $y = 0$  if she does not.  $x$  is a 8-dimensional vector containing the eight features (including a one for the constant term that models the intercept). The

Variable	Data type	Meaning	Role
Work	Binary	Whether or not the woman works	Response
Constant	1	Constant to the intercept	Feature
HusbandInc	Numeric	Husband's income	Feature
EducYears	Counts	Years of education	Feature
ExpYears	Counts	Years of experience	Feature
ExpYears2	Numeric	(Years of experience)/10)^2	Feature
Age	Counts	Age	Feature
NSmallChild	Counts	Number of child <7 years in household	Feature
NBigChild	Counts	Number of child >6 years in household	Feature

goal is to approximate the posterior distribution of the 8-dim parameter vector  $\beta$  with a multivariate normal distribution

$$\beta|y, X \sim N(\hat{\beta}, J_y^{-1}(\hat{\beta}))$$

where  $\hat{\beta}$  is the posterior mode and  $J(\hat{\beta}) = -\frac{\delta^2 \ln p(\beta|y)}{\delta\beta\delta\beta^T}|_{\beta=\hat{\beta}}$  is the observed Hessian evaluated at the posterior mode. Note that  $J(\hat{\beta})$  is an 8x8 matrix with second derivatives on the diagonal and cross-derivatives  $\frac{\delta^2 \ln p(\beta|y)}{\delta\beta_i\delta\beta_j}$  on the offdiagonal. It is actually not hard to compute this derivative by hand, but don't worry, we will let the computer do it numerically for you. Now, both  $\hat{\beta}$  and  $J(\hat{\beta})$  are computed by the `optim` function in R. I want you to implement your own version of this. You can use my code as a template, but I want you to write your own file so that you understand every line of your code. Don't just copy my code. Use the prior  $\beta \sim N(0, \tau^2 I)$ , with  $\tau = 10$ . Your report should include your code as well as numerical values for  $\hat{\beta}$  and  $J(\hat{\beta})$  for the `WomenWork` data.

Compute an approximate 95% credible interval for the variable *NSmallChild*. Would you say that this feature is an important determinant of the probability that a women works?

NSmallChild

-2.1141903

-0.5896295

The number of small children seem to matter. The coefficient is by far the largest, especial compared to the number of larger children a woman has. This would also intuitivaly make sense, because the earlier years of a childs life it demands more attention and it would therefore be more likely for one of the parents to remain at home and not have a job.

**b.**

Write a function that simulates from the predictive distribution of the response variable in a logistic regression. Use your normal approximation from 2(a). Use that function to simulate and plot the predictive distribution for the Work variable for a 40 year old woman, with two children (3 and 9 years old), 8 years of education, 10 years of experience. and a husband with an income of 10. [Hints: The R package mvtnorm will again be handy. Remember my discussion on how Bayesian prediction can be done by simulation.]

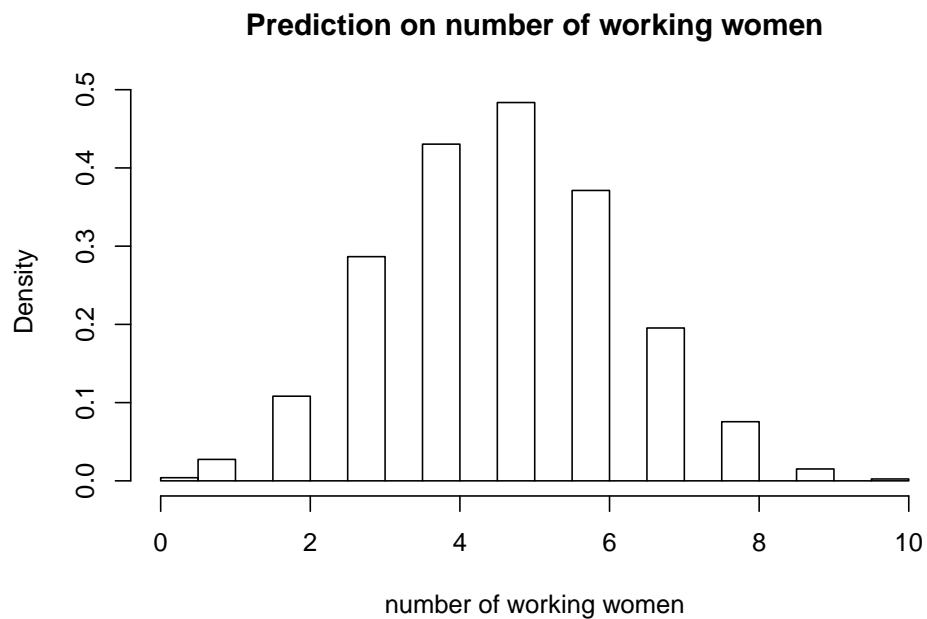

## The expected value for this woman is: 0.4775278 , thus the model predicts that she is working.

**2c.**

Now, consider 10 women which all have the same features as the woman in 2(b). Rewrite your function and plot the predictive distribution for the number of women, out of these 10, that are working. [Hint: Which distribution can be described as a sum of Bernoulli random variables?]

Now, we have  $n=10$  random variables and the probability of working(success) = 0.4775278, then we use binomial distribution to calculate the probability of working.
